

ABSTRACT

A structural improvement of the push key for conventional telephones, mobile phones and computer sets, particularly a key made of conductive or non-conductive materials, optionally having a depression at the center of the key, and a touch spot at the middle of the depression, so when an operator's finger touches lightly or comes near the key or the touch spot, the key senses the touch or approach and creates a specified signal to control the dialing of a number or other functional control, preventing poor connection of the key, ensuring every key to create necessary signals, and reduce wear and tear on the words or icons printed on the surface of the key, to simplify operating procedures for the operator.

V. (i) Representative figure in this case: Figure 7.

(ii) Brief description of numerals in this case:

5 faceplate	50 keyhole
6 key body	7 circuit board
